Recap

- What things do we need to define in order to formulate a problem as a search problem?

Env

State

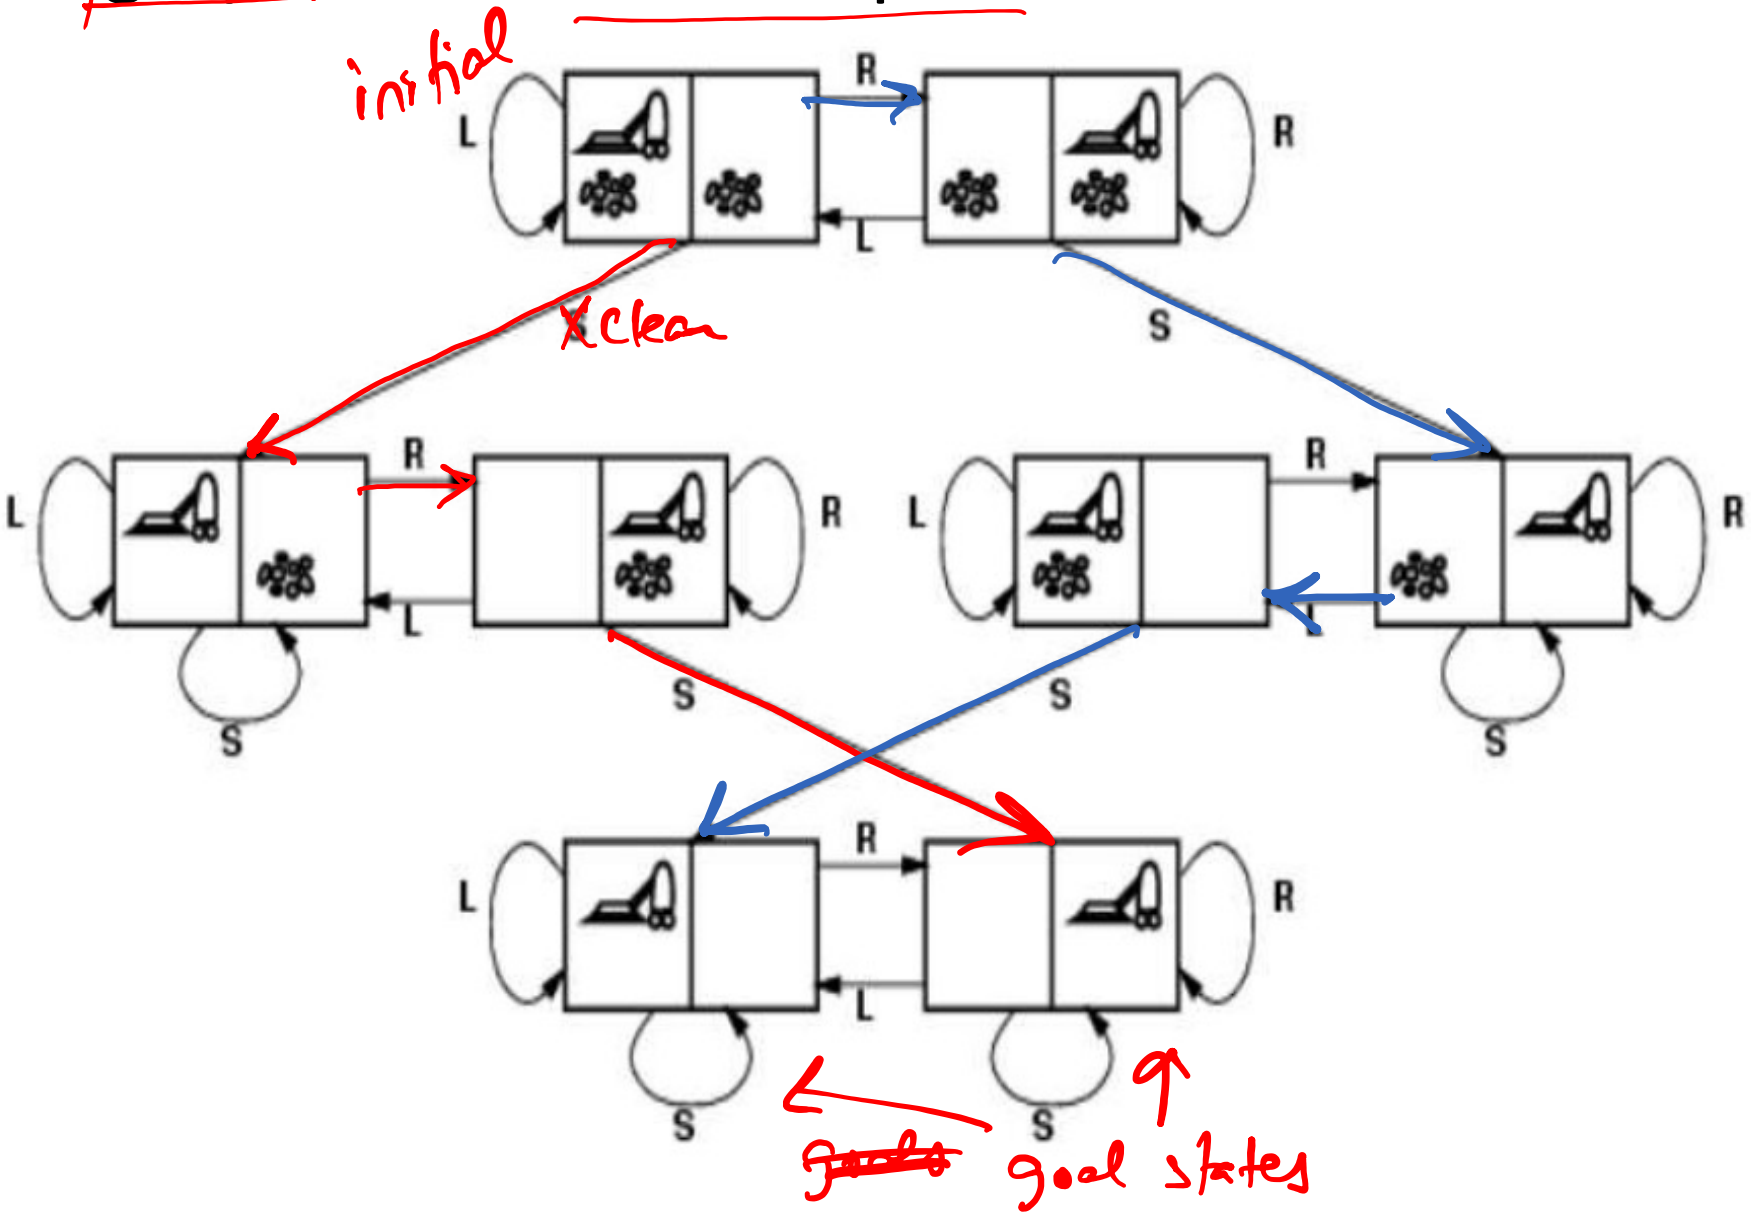
Initial State

Actions

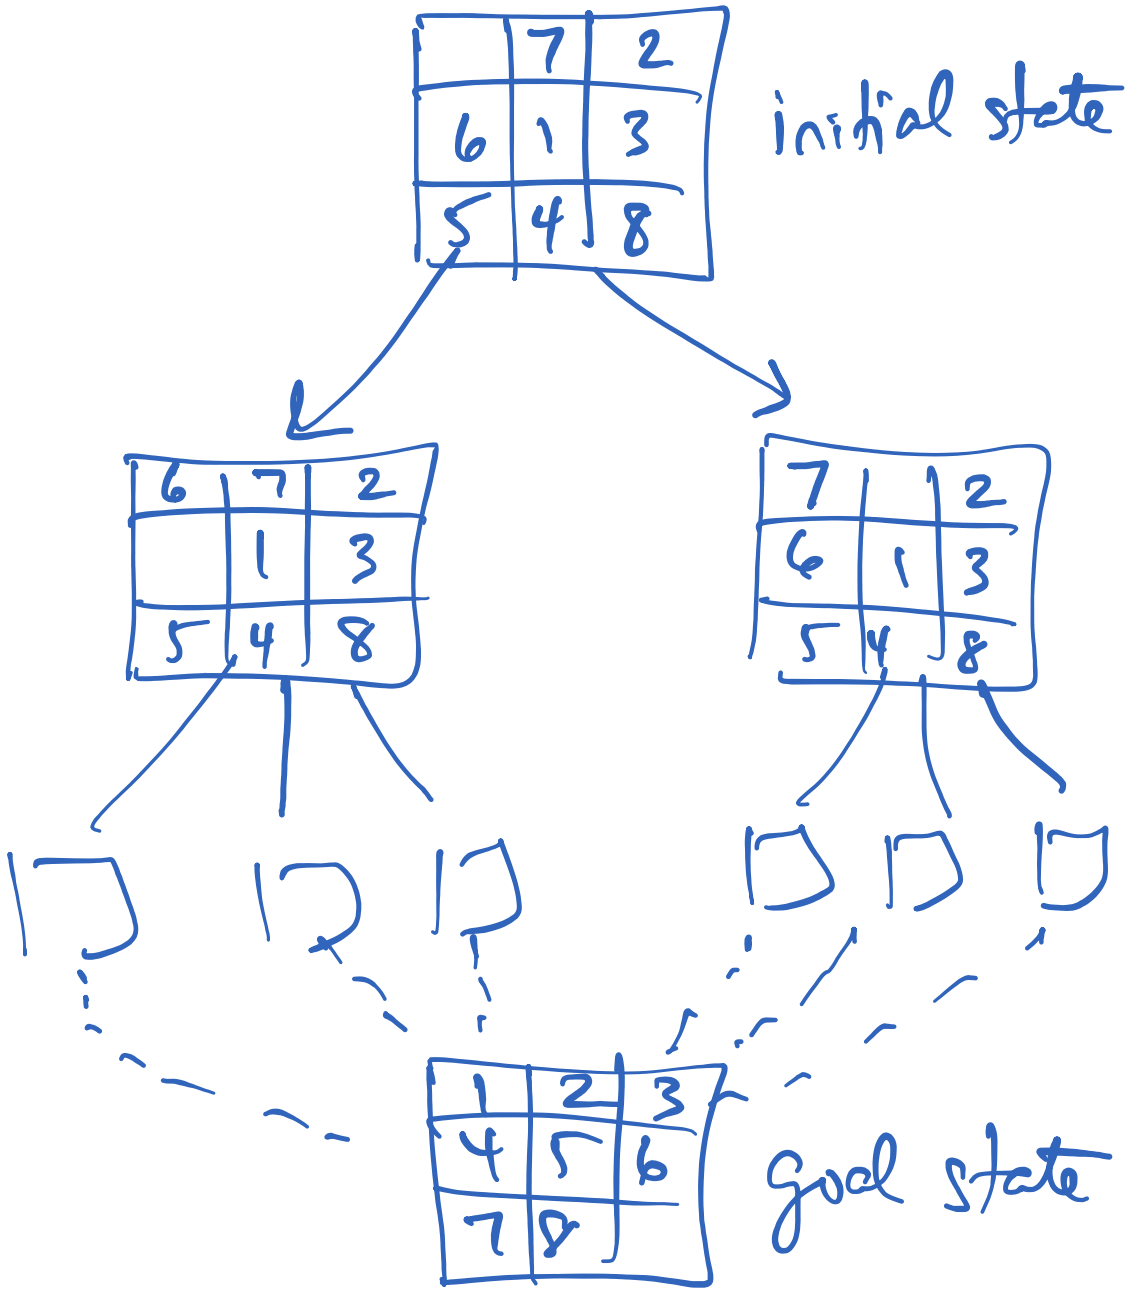
Goal state

Cost

- Always a good idea to try to visualize the graph of the search space.



8-puzzle/sliding block puzzle



graph

Generic search algorithms (3.3)

- All search algorithms work in essentially the same manner:
- Start with initial state.
- Generate all possible successor states (*a.k.a.* "expanding a node."
- Pick a new node to expand.
- Continue until we find a goal state.

"next states"

← Differentiates each algorithm.

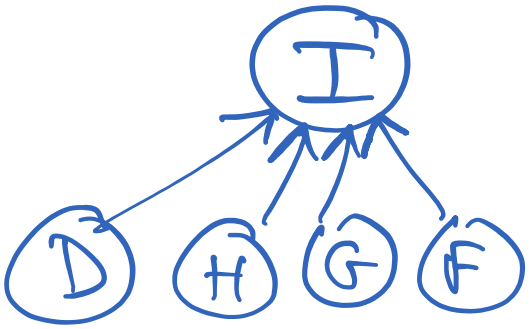
Node vs State

- There are two simultaneous graph-like structures used in search algorithms:
  - (1) Tree or graph of the underlying state space.
  - (2) Tree maintaining the record of the current search in progress (the ***search tree***).
- (1) does not depend on the current search being run.
- (1) is sometimes not even stored in memory (too big!)
- (2) always depends on the current search, and is always stored in memory. It is created on the fly during the running of the search algorithm.

Search tree



- A node ***n*** of the search tree stores:
  - a state (of the state space)
  - a pointer to the state's parent node (usually)
  - the action that got you from the parent to ***n*** (sometimes)
  - the path cost $g(\boldsymbol{n})$: cost of the path *so far* from the initial state to ***n***.

Generic search algorithms

(all based off of "best-first search")

- ***Frontier:*** a data structure storing the collection of nodes that are available to be examined next in the algorithm.
  - Often represented as a stack, queue, or priority queue.
- ***Reached:*** a map from nodes to states. Keeps track of which states have been examined already.
  - Often stored using a data structure that enables quick look-up for membership tests.

key value

hash table

BST

How do you evaluate a search algorithm?

- **Completeness** — Does the algorithm always find a solution if one exists?
- **Optimality** — Does the algorithm find the best solution?
- **Time complexity**
- **Space complexity**

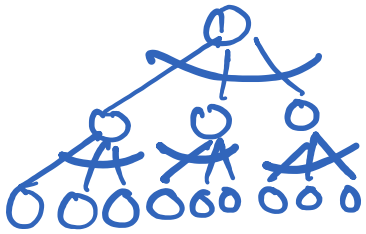
Uninformed search methods

- These methods have no information about which nodes are on promising paths to a solution.
- Also called: *blind search*

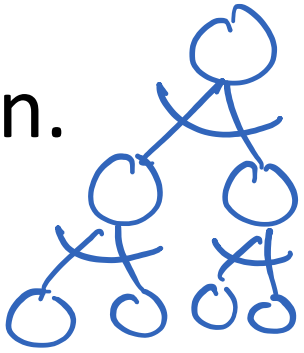
Uninformed Search algorithms

- Breadth-first search
- Uniform-cost search
- Depth-first search

```
function BREADTH-FIRST-SEARCH(problem) returns a solution node or failure
  node ← NODE(problem.INITIAL)
  if problem.IS-GOAL(node.STATE) then return node
  frontier ← a FIFO queue, with node as an element
  reached ← {problem.INITIAL}
  while not IS-EMPTY(frontier) do
    node ← POP(frontier)
    for each child in EXPAND(problem, node) do
      s ← child.STATE
      if problem.IS-GOAL(s) then return child
      if s is not in reached then
        add s to reached
        add child to frontier
  return failure
```



Breadth-first search



- Choose shallowest node for expansion.
- Data structure for frontier?
  - Queue (regular)
- Complete? Optimal? Time? Space? — $O(b^d)$

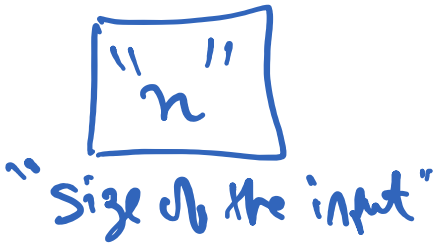
Yes

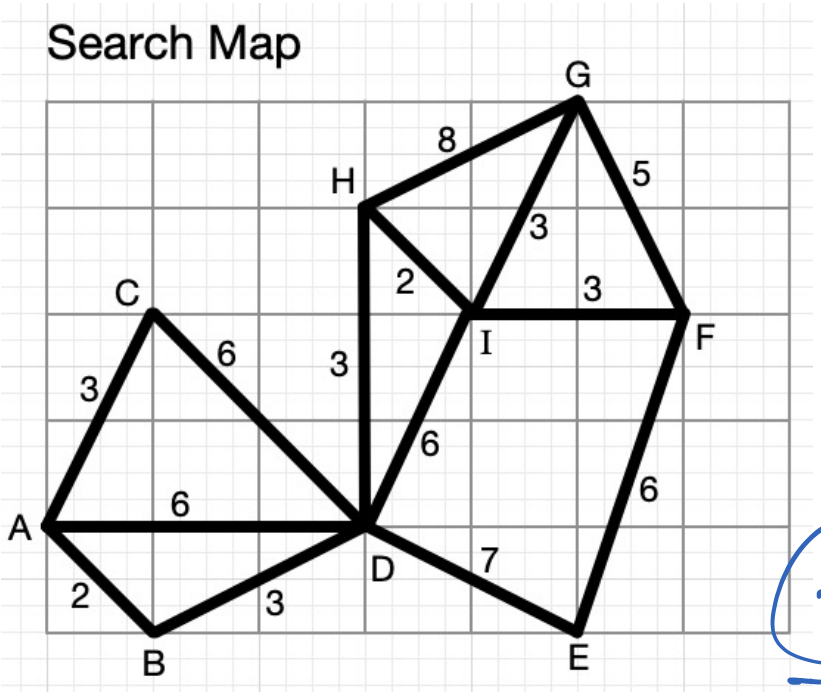
No, unless.... all costs are the same

(b) branching factor: max # of actions from a state

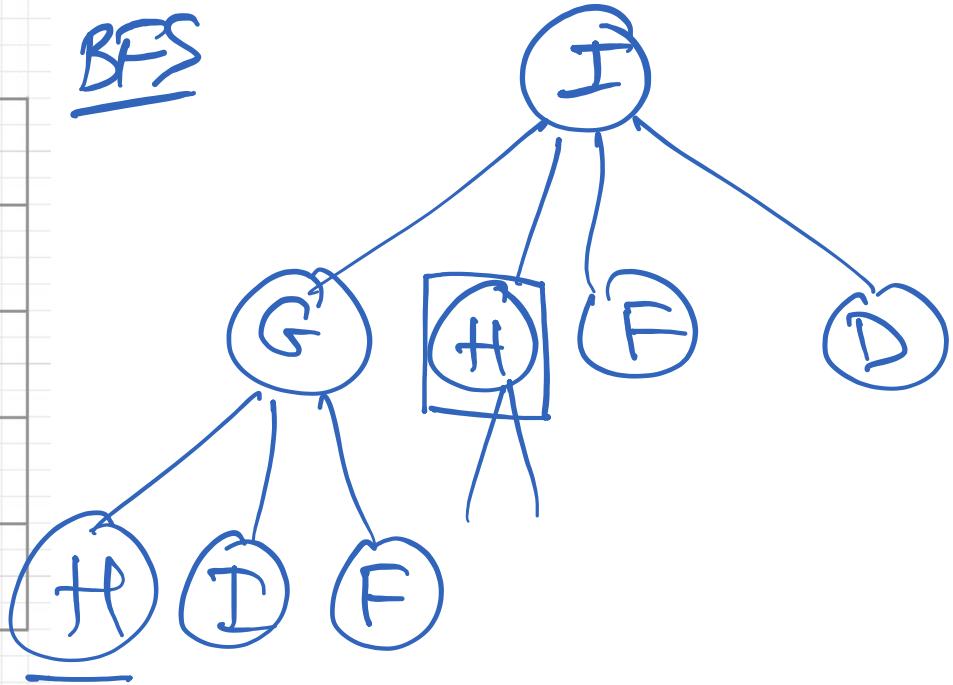
(d) depth of the solution in the search tree

$O(b^d)$





BFS



Depth-first search (DFS)

- Choose deepest node to expand.
- Data structure for frontier?
  - Stack (or just use recursion)
- Complete? Optimal? Time? Space?

No, unless you prevent loops. (Yes, if you do)

No

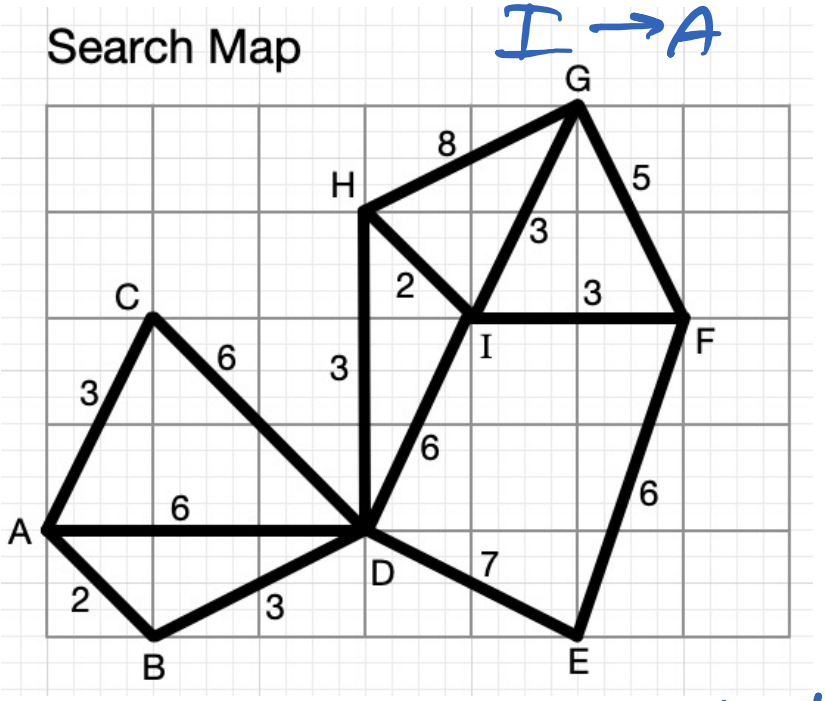
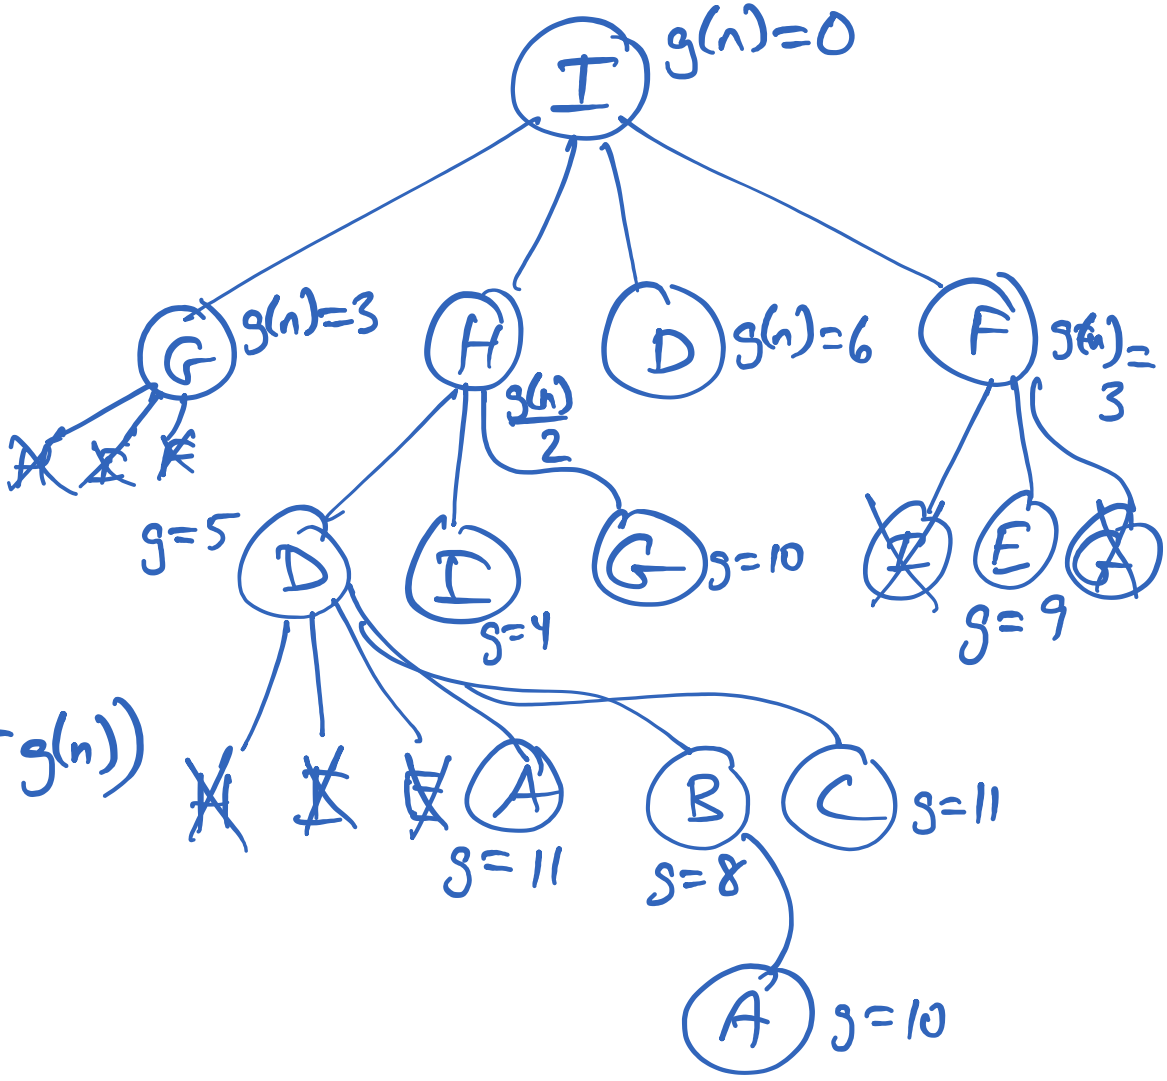
Dijkstra = Uniform-cost search

total cost so far from initial state to n

- Choose node with lowest path cost g(n) for expansion.
- Data structure for frontier?
  - Priority queue
- Suppose we come upon the same state twice. Do we re-add to the frontier?
  - Yes, if lower path cost.





Frontier (sorted by lowest g(n))
